We present a sample of 8 Seyfert 2 galaxies observed by 
HST, Chandra and XMM-Newton. All of the sources 
present soft X-ray emission which is coincident in ex-
tension and overall morphology with the [O\text{III}] emis-
sion. The spectral analysis reveals that the soft X-ray 
emission of all the objects is likely to be dominated by 
a photoionized gas. We tested with the code CLOUDY a 
simple scenario where the same gas photoionized by the 
nuclear continuum produces both the soft X-ray and the 
[O\text{III}] emission. Solutions satisfying the observed ratio 
between the two components exist, and require the den-
sity to decrease with radius roughly like $r^{-2}$, similarly to 
what often found for the Narrow Line Region.

Key words: galaxies: Seyfert - X-rays: galaxies.

1. THE SAMPLE

The sample consists of all the Seyfert 2 galaxies included 
in the Schmitt et al. (2003) catalog, with a Chandra ob-
servation, with the only exclusion of NGC 1068, which 
has already been extensively studied. On the other hand, 
we added another source, NGC 5643. All the sources 
have also an XMM-Newton RGS observation, except for 
NGC 5347.

2. ANALYSIS

2.1. Imaging

Figure 1 shows the contours of the Chandra soft X-ray 
emission superimposed on the HST [O\text{III}] images, for 
all the sources in our sample. The coincidence between 
the soft X-ray and [O\text{III}] emission is striking, both in the 
extension and in the overall morphology. Unfortunately, 
the lower spatial resolution of Chandra with respect to 
HST does not allow us to perform a detailed comparison 
of the substructures apparent in the latter.

2.2. Spectral analysis

The spectral analysis of the sources suggests that the most 
likely origin for the soft X-ray emission is in a gas pho-
toionized by the nuclear continuum. In spectra with CCD 
resolution, a ‘scattering’ model (a powerlaw plus emis-
sion lines) is to be preferred to a ‘thermal’ model either 
on statistical grounds or because of unphysical best fit 
parameters of the latter (quasi-zero abundances). On the 
other hand, the RGS spectra are clearly dominated by 
emission lines, with a very low level of continuum (Fig. 
3, 4, 5). This allows us to easily detect strong emission 
lines even in short observations of objects with relatively 
low fluxes. The clearest piece of evidence comes from 
the 190 ks combined RGS spectrum of Mrk 3, which is 
produced in a photoionized gas with an important contri-
bution from resonant scattering.

The other spectra do not have enough statistics to allow 
us to draw unambiguous conclusions on any individual 
object. The predominance of the forbidden transition of 
the O\text{VII} triplet is a common feature of all spectra, ex-
cept for NGC 5643. Deeper high-resolution observations 
of our sample will be able to confirm whether photoion-
ization by the AGN is indeed the dominant mechanism 
responsible for the soft X-ray emission in these objects.

3. PHOTONIZATION MODELS

The spectral analysis of the sources in our sample sug-
ests that their soft X-ray spectra are likely dominated by 
emission lines produced in a material photoionized by the 
central AGN. On the other hand, the striking resemblance 
of [O\text{III}] structures with the soft X-ray emission favors 
a common origin for both components. Therefore, since 
the NLR is generally believed to be also produced mainly 
by photoionization, we generated a number of models in
Figure 1. Chandra soft X-ray contours superimposed on HST [OIII] images. The contours correspond to five logarithmic intervals in the range of 1.5-50% (NGC 1386), 5-80% (Mrk 3), 5-90% (NGC 3393), 4-50% (NGC 4388), 0.5-50% (NGC 4507) and 2-50% (NGC 5347) of the peak flux. The HST images are scaled with the same criterion for each source, with the exception of NGC 4388 and NGC 4507, whose [OIII] emission goes down to the 2% and the 0.1% of the peak, respectively.
order to investigate if a solution in terms of a single photoionized material to produce the optical NLR and the soft X-ray emission is tenable. Calculations were performed with version 96.01 of CLOUDY, last described by Ferland et al. (1998). The adopted model is represented by a conical geometry, which extends from 1 to 350 pc from the nucleus, with temperature set by photoionization equilibrium under a typical AGN continuum (Korista et al. 1997). We produced a detailed grid of models, as a function of the following parameters: ionization parameter $U$ of the illuminated face of the gas; filling factor of the gas $f$; density of the gas $n_e$. We assume a power-law radial dependence of the density, $n_e(r_0) \left( \frac{r}{r_0} \right)^{-\beta}$, with $\beta = 0$ (constant density) and varying between 1 and 2.4. We limit our models to a minimum total column density of $10^{20}$ cm$^{-2}$.

The ratio between the [O III] $\lambda$5007 line and the soft X-ray emission (defined as the total flux of the Kα and Kβ emission lines from N, O, Mg, S, Si in the range 0.5-2.0 keV) was calculated for each set of parameters. In the left panel of Fig. 6, each symbol represents a solution in the $U$ versus $n_e$ plane, where this ratio has a value within 2.8 and 11, as observed in our sample. Different symbols correspond to different values of $\beta$. The net effect of changing the filling factor is simply a shift of the solutions along the density axis, by a factor equivalent to the variation in $f$, thus reproducing the same total column density for each set of three parameters constituting a ‘good’ solution. The solutions occupy well-defined regions in the $n_e - U$ diagram, with those with lower $\beta$ being at larger values of ionization parameters.

The reason for this behaviour becomes clear inspecting the right panel of Fig. 6, where the [O III] to soft X-ray flux ratio is plotted as a function of the radius of the gas. Since $U \propto n_e^{-1} r^{-2}$, all density laws with $\beta < 2$ produce a gas with a ionization parameter decreasing along with the distance. In these cases ($\beta = 1.6$ and 1.8 in Fig. 6), most of the soft X-ray emission is produced in the inner radii of the cone, while the bulk of the [O III] emission is produced farther away, where the gas is less ionized. If $\beta = 2$, the ionization parameter remains fairly uniform up to large radii, so that the total observed ratio between [O III] and soft X-ray is constant with radius. Finally, if $\beta > 2$, the ionization parameter increases with radius, so most of the soft X-rays are actually produced at larger radii, while the [O III] emission line is mostly concentrated around the nucleus (cases $\beta = 2.2$ and 2.4 in Fig. 6). This is the reason why solutions with $\beta < 1.6$ and $\beta > 2.4$ are not plotted in Fig. 6, even if these exist, satisfying the overall [O III] to soft X-ray flux ratio. Their radial behaviour is radically different from what seen in Fig. 1 and 2, where both the [O III] and the soft X-ray emission are produced up to large radii. In particular, it is worth noting that constant-density solutions are totally unacceptable. A detailed analysis, as presented in Bianchi et al. (2005, submitted), suggests that the [O III] to soft X-ray flux ratio observed in the sources of our sample remains fairly constant up to large radii, thus requiring that the density decreases roughly like $r^{-2}$, similarly to what often found for the Narrow Line Region.

REFERENCES

Figure 3. Combined RGS1/RGS2 spectrum plotted in the rest frame of the source (12-25 Å), for NGC 1386 (17 ks, $F_{0.5-2 keV} = 1.8 \times 10^{-13}$ cgs), Mrk 3 (190 ks, 4.7) and NGC 3393 (14 ks, 2.2).
Figure 4. Same as Fig. 3, for NGC 4388 (12 ks, 3.4), NGC 4507 (46 ks, 3.3) and NGC 5643 (10 ks, 1.4).
Figure 5. Same as Fig. 3, for NGC 7212 (14 ks, 0.8).

Figure 6. Left: Each symbol represents one solution in our grid of CLOUDY models that satisfies the condition of total $[\text{O}\text{ III}]$ to soft X-ray flux ratio in the range observed in our sample, plotted in a three-parameter space $U$, $n_e$ and $\beta$, i.e. the ionization parameter and the density at the beginning of the cone of gas (1 pc), and the index of the density powerlaw, represented by different symbols (triangles: $\beta = 1.6$, diamonds: $\beta = 1.8$, stars: $\beta = 2.0$, squares: $\beta = 2.4$). The horizontal lines determine the limit corresponding to a total column density of $10^{20}$ cm$^{-2}$ for each index: solutions below this limit are not plotted. Solutions with $\beta = 2.2$ are not plotted for clarity reasons. The net effect of the filling factor $f$ is to shift the density values: the two y axes refer to $f = 0.1$ and $f = 0.01$ (see text for details). Right: The $[\text{O}\text{ III}]$ to soft X-ray ratio plotted as a function of the radius of the gas, for different values of $\beta$, when $\log n_e = 3$ and $f = 0.1$. The corresponding values of $\log U$ for these solutions are (from top to bottom): -0.85, -1.15, -1.4, -1.5, -1.6.
