ABSTRACT

The results from massive multiwavelength follow-up campaigns of X–ray sources discovered in both deep and shallow Chandra and XMM-Newton surveys have revealed a population of X-ray emitting Extremely Red Objects (X-EROs). We present the results obtained from the combined analysis of 80 ks XMM-Newton and 90 ks Chandra observations of a complete sample of optically selected EROs, with particular emphasis on the relationship between X-EROs and high luminosity, obscured quasars (QSO2). We also present several, independent findings indicating that a large fraction of X-EROs are hosted among the most massive galaxies at z=1-2, and thus can be used as lighthouses to investigate the link between the formation of massive ellipticals and the onset of AGN activity.

Key words: X–rays: surveys, galaxies: active, galaxies: Extremely Red Objects.

1. INTRODUCTION

Extremely Red Objects (EROs, R−K>5, Elston et al. 1988), initially detected in near–infrared ground–based imaging, have the colors expected for high-redshift passive ellipticals and have been used as tracers of distant (z> 1) and old spheroids. Reproducing their observational properties has proved to be extremely challenging for all current galaxy formation models. However, on the basis of a number of observational results, it has been pointed out that high-redshift passive ellipticals are only one of the various classes of extragalactic sources which make up the ERO population. Deep VLT spectroscopy from the K20 survey (Cimatti et al., 2002) has indeed shown that EROs are nearly equally populated by old, passively evolving systems and dusty star–forming galaxies over a similar range of redshift (z = 0.8 – 2 for both classes) and similar results are confirmed by both colour selection criteria (Mannucci et al., 2002) and by radio observations (Smail et al., 2002). A few individual objects have been also identified as high redshift (z=1–1.5) Active Galactic Nuclei (AGN) on the basis of the detection of strong emission lines in near–infrared and/or optical spectra (see e.g. Pierre et al. 2001).

A population of optically faint X–ray sources without any obvious AGN signature in the optical spectrum and with optical to near–infrared colors typical of high redshift ellipticals and starburst galaxies has been revealed in the deepest Chandra and XMM–Newton exposures (e.g. Hasinger et al. 2001; Barger et al. 2003; Szokoly et al. 2004). It has been suggested that the AGN population among EROs has the same X–ray properties of high–luminosity, highly obscured (NH > 10¹²² cm−²) Type 2 Quasars (Mainieri et al., 2002; Alexander et al., 2002; Brusa, 2003). Further support for the result that a significant fraction of obscured AGN are hosted in EROs comes from near infrared observations of X–ray sources selected on the basis of their high X–ray to optical flux ratio (X/O> 10, Mignoli et al. 2004): the hosts of luminous, obscured hard X-ray sources with extreme X/O are among the most massive spheroids at z> 1.

The observed fraction of AGN among EROs can therefore help constraining models for the joint evolution of supermassive black holes and galaxies bulges (e.g. Granato et al. 2004; Merloni 2004; Marconi et al. 2005). Previous studies on the fraction of AGN among the EROs population, although having deep near–infrared and X–ray observations (K ∼ 21 – 22 and the Megaseconds Chandra exposures) were limited in areal coverage (50–80 arcmin²) and therefore were not suitable for detailed statistical analyses of the AGN EROS population.

We will briefly discuss how it is possible, combining near–infrared and X–ray data over a significantly larger area, to constrain the fraction of AGN EROS in near infrared selected samples and the masses of the black holes powering the X–ray emission in these sources.
2. THE XMM-NEWTON SURVEY OF EROS IN THE DADDI FIELD

2.1. X–ray data

We have started an extensive program of multiwavelength observations of the largest sample of near–infrared selected EROs available to date (~400 sources), selected over a contiguous field of ~ 700 arcmin$^2$ (the “Daddi field”, Daddi et al. 2000). The sample is complete to a magnitude limit of $K_s$ ~19 and the field is covered by deep optical photometry in the R–band ($R$ ~26).

We have obtained with XMM–Newton a total of about 110 ks observing time, splitted in three different pointings (Brusa et al., 2005). The area analysed in the present work is ~ 380 arcmin$^2$ (see Fig. 1) and covers the region with a uniform coverage in the optical and near–infrared bands. The detection algorithm developed for the Hellas2Xmm survey (see Baldi et al. 2002 for details) was run on the 2–10 keV (hard band) cleaned events: 60 sources were detected down to a limiting flux of $S_{2-10} \sim 4 \times 10^{-15}$ erg cm$^{-2}$ s$^{-1}$. The central (380 arcmin$^2$) region of the Daddi Field has been subsequently imaged also by Chandra, with a mosaic of 3×30 ks, partially overlapping observations. Data were processed using version 3.2.1 of the CIAO software and mosaiced with the merge_all script. The full band (0.5-7 keV) Chandra mosaic is shown in Fig. 1.

2.2. Optical identifications

At the faint X-ray and optical fluxes probed by the present survey the identification process of XMM sources is not straightforward due to the positional uncertainties associated with the XMM Point Spread Function. In order to identify the correct optical counterparts and to assess the statistical significance of the X-ray to optical associations we have used the “likelihood ratio technique” (Sutherland & Saunders, 1992). We were able to reliably identify ~ 80% of the X-ray sources, while for the remaining ~ 20% of the sources we were not able to provide an unambiguous association due to the faintness of the flux density in the direction of the field ($N_{HI}=5 \times 10^{20}$ cm$^{-2}$, Dickey & Lockman 1990), and weighted by the effective exposure times of the different EPIC cameras.
possible counterparts (R>24) or to the presence of multiple sources, with similar likelihoods of being the correct identification, within the XMM error circles.

The XMM–Newton area analysed in this work includes 257 EROs: 173 EROs with $K_s < 18.8$ over $\sim 380 \text{arcmin}^2$, and 216 EROs with $K_s < 19.2$ in the area in common with the deeper near-infrared coverage ($\sim 300 \text{arcmin}^2$, see Fig. 1). Nine of the 257 EROs which fall within the XMM–Newton area are individually detected in the hard (2-10 keV) band. We checked our X–ray to EROs associations with the available Chandra data: all nine XMM–Newton detected EROs have been detected also by Chandra and in all the cases, thanks to the much sharper positional accuracy, the Chandra X–ray centroid points unambiguously to the candidate optical counterpart, further assessing the reliability of the adopted method for the identification of XMM–Newton sources. The finding charts of 6 X–ray emitting EROs in the R–band with superimposed the XMM-Newton error circle (5′′) and the Chandra contours are shown in Fig. 2.

3. RESULTS FROM OUR SURVEY

In the XMM–Newton observation, the X–ray limiting flux corresponds to an X–ray luminosity $L_X \sim 10^{43} \text{erg s}^{-1}$ for $z=1$. Thus, the EROs X–ray emission is most likely powered by AGN activity, and the fraction of AGN among EROs in the present sample is at least $3.5 \pm 1.7\%$ (9/257). Conversely, the fraction of EROs among the hard X–ray population is much higher ($\sim 15\%$). The fraction of X–ray detected EROs in K–selected samples has been reported by Alexander et al. (2002; hereinafter A02) and Roche, Almaini & Dunlop (2003; hereinafter R03) at different X–ray and K–band limiting fluxes. Combining the depth of the different samples with the observed X–ray to optical flux ratios distribution (see Next Section), it is possible to derive an estimate of the fraction of AGN EROs among K–selected samples as a function of the K–band magnitude only and independently from the X–ray limiting fluxes (see Brusa et al. 2005 for details). Figure 3 compares the fraction of AGN in our sample with those in the A02 and R03 samples and suggests that the fraction of AGN EROs among the K–selected EROs population is an increasing function of the K–band magnitude. The results from hard X–ray surveys indicate a space density of low–luminosity ($10^{42} - 10^{44} \text{erg s}^{-1}$) AGN which is almost two orders of magnitudes higher than that of high luminosity sources (Fiore et al., 2003; Ueda et al., 2003). Thus, it is not surprising that the fraction of AGN EROs increases going toward faint fluxes (i.e., lower luminosities). It is worth remarking that the fraction of “active” objects in K–selected EROs samples can be used to constrain models which link the formation and evolution of galaxies and AGN (e.g. Merloni 2004).

Figure 2. Finding charts in the R–band of 6 out of the nine X–ray emitting EROs in the Daddi Field. Large open circles (5′′ radius) are centered on the XMM-Newton position; small red circles (1′′ radius) mark the proposed EROs counterparts; green contours represent the Chandra sources.

Figure 3. Fraction of AGN ERO as a function of the K–band magnitudes, as computed from three different samples: this work, the Alexander et al. sample (A02) and the Roche et al. sample (2003). The large errorbars associated with the A02 and R03 points are mostly due to the small area covered.
4. X-RAY TO OPTICAL PROPERTIES

In order to investigate the nature of hard X-ray selected EROs and the link between faint hard X-ray sources and the ERO population, we have collected from the literature a sample of 128 X-ray detected EROs (including the 9 objects previously described). For about half of them (62/128) photometric or spectroscopic redshifts are available (data from: Mainieri et al. 2002; Barger et al. 2003; Willott et al. 2003; Brusa et al. 2005; Crawford et al. 2002; Szokoly et al. 2004; Mignoli et al. 2004). This sample is by no means homogeneous (e.g. the selection criteria for EROs are slightly different, R-K > 5 or I-K > 4 depending on the authors; or the K-coverage is not complete), but could be considered representative of EROs individually detected in the X-rays. The R-band magnitudes plotted versus the hard X-ray fluxes are reported in Fig. 4 (left panel): about half of the sources show an X-ray–to–optical flux ratio (X/O) larger than 10, shifted up by one order of magnitude from that of broad-line AGN, confirming independent results from near infrared observations of X-ray sources selected on the basis of their high X/O (e.g. Mignoli et al. 2004; Maiolino et al. 2005). On the contrary, when the X-ray to near-infrared properties are considered, all the X-ray detected EROs in the comparison sample occupy a locus which is indistinguishable from that occupied by unobscured QSO (Fig. 4, right panel). This result further corroborates the hypothesis that AGN EROs are obscured quasars.

5. X-RAY PROPERTIES OF AGN EROS

High obscuration in X-ray detected EROs is also revealed in the X-ray band, in agreement with the results from the optical band. The average hardness ratio of the hard X-ray detected EROs in our XMM–Newton observation suggests substantial column densities at the source redshift. We have quantitatively estimated the intrinsic X-ray column densities for the 62 EROs in the comparison sample with a reliable spectroscopic or photometric identification. The results are reported in Fig. 5 (left panel). Almost all of the individually detected EROs have intrinsic $N_H > 10^{22} \text{cm}^{-2}$, and they actually are heavily obscured AGN. This study confirms previous evidences mainly based on a Hardness Ratio analysis (A02) and on few isolated examples (e.g. Stevens et al. 2003; Severgnini et al. 2005), and unambiguously indicates that large columns of cold gas (even $> 10^{23} \text{cm}^{-2}$) are the rule rather than the exception among X-ray bright EROs.

5.1. EROs and QSO2: a selection criterion

Given the high-redshift ($z > 0.8$) and the average X-ray flux ($\sim 4 \times 10^{-15} \text{erg cm}^{-2} \text{s}^{-1}$) of these objects, it is not surprising that the majority of X-ray detected EROs have high X-ray luminosities ($L_X > 10^{43} \text{erg s}^{-1}$). Moreover, according to our analysis, a significant fraction of them have X-ray luminosities exceeding $10^{44} \text{erg s}^{-1}$,
Figure 5. Left panel: Logarithm of the absorbing column density ($N_H$) versus the logarithm of the unabsorbed X–ray luminosity in the 2-10 keV band for all the X–ray detected EROs with spectroscopic or photometric redshifts from the literature sample. Filled symbols are those with X/O $> 10$ (see text). In the upper right corner the “QSO2 locus” is highlighted. Right panel: The $M_{BH}$ obtained applying the Marconi & Hunt (2003) relation for the identified EROs versus the $L_X$. Symbols as in Fig. 4. Filled circles are sources with spectroscopic redshift. The continuous lines represent the expected correlation between the two plotted quantities for two different assumptions on the bolometric correction and $L_{bol}/L_{Edd}=1$.

and therefore lie within the quasar regime (see also Servenini et al. 2005, and this volume). The large intrinsic column densities further imply that AGN EROs, selected at bright X–ray fluxes, have properties similar to those of QSO2, the high–luminosity, high–redshift Type 2 AGNs required by X–Ray Background synthesis models (Comastri et al., 2001; Gilli et al., 2001). Among the X–ray detected EROs, the higher is the luminosity, the higher is the X–ray to optical flux ratio (filled symbols in left panel of Fig. 5). This confirms that a selection based on X/O $> 10$ is a powerful tool to detect high–luminosity, highly obscured sources (see Fiore et al. 2003) and it is even stronger when coupled with a previous selection on the extremely red colors. Given that the search for QSO2 on the basis of detection of narrow optical emission lines is extremely time consuming and also already challenging the capabilities of the largest optical telescopes, all the findings discussed above support the idea that hard X–ray surveys coupled with near–infrared observations provide an efficient method in detecting QSO2.

5.2. The masses and level of activity of X-ray emitting EROs

Indipendent arguments suggest that the near–infrared emission of X–ray selected obscured AGN is dominated by their host galaxy starlight (see e.g. Maiieri et al. 2002; Mignoli et al. 2004). Using the correlation between the bulge K–band luminosity and the BH mass published by Marconi & Hunt (2003), it is possible to estimate the masses of the obscured SMBH powering the X–ray emission of the 62 EROs with redshift information in the literature sample and the 9 EROs of the present work for which redshifts and luminosities have been estimated from the Fiore et al. (2003) relation. The BH masses have been computed assuming that 1) the measured K band light is completely due to the bulge component and therefore the AGN emission does not significantly contribute to the near-IR light and that 2) the shape of the Marconi & Hunt (2003) relation does not significantly evolve with redshift and/or luminosity. The $M_{BH}$ obtained through a chain of assumptions and neglecting the uncertainties associated to the observed relations, are plotted versus the $L_X$ in the right panel of Fig. 5. We note that the presence of a disk or a residual point–source contribution would lower the bulge luminosity and in turn the mass determination, that can therefore be considered as conservative upper limits. The absorption corrected X–ray luminosity can be translated into a bolometric luminosity assuming a bolometric correction factor ($L_{bol} = k_{bol} \times L_X$). The continuous lines in the right panel of Fig. 5 represent the relation between the BH mass and the X–ray luminosity in the hypothesis of Eddington limit accretion ($L_{bol}/L_{Edd} = 1$) and for two different values ($k_{bol}=10$ and $k_{bol}=30$) of the

$^2$A robust estimate for the bolometric correction ($k_{bol} \sim 30$) is available only for bright unobscured quasars (Elvis et al., 1994); lower values ($k_{bol} \sim 10–20$) appear to better reproduce the observed spectral energy distribution of Seyfert like galaxies (Fabian, 2004) and of a few heavily obscured, luminous sources (Comastri, 2004).
bolometric correction. Despite the large scatter observed in Fig. 5 – for a given BH mass the corresponding luminosity ranges up to 2 orders of magnitudes – there is a clear trend between the X-ray luminosity and the BH mass; the dispersion can be reasonably well explained by a spread in the Eddington ratios in the range $L_{\text{bol}}/L_{\text{edd}} = 10^{-3} - 10^0$, most of the sources having $L_{\text{bol}}/L_{\text{edd}} > 10^{-2}$. Both the BH masses and the Eddington ratios derived above are consistent with a scenario in which X-ray detected EROs are obscured quasars emitting in a radiatively efficient way, in agreement with the results of Merloni (2004) and McLure & Dunlop (2004).
