

X-ray grating observations of novae

Marina Orio, Dublin, June 2014

Two distinct components:

- ◆ The luminous supersoft component associated with the white dwarf atmosphere (up to a few 10^{38} erg/s)
- ◆ X-ray emission from the ejecta (up to 10^{36} erg/s)
- ◆ The initial motivation to study novae was to probe the white dwarf atmosphere and obtain the mass and chemical composition of the WD (Ögelman et al. 1983+)
- ◆ Immediately, it became clear that there may be X-ray emission from the ejecta and that broad band spectra may be insufficient to disentangle them (problem of $N(H)$).

Hard X-ray emission as a way to test how mass loss occurs:

- ◆ Is hard X-ray emission correlated with the gamma ray emission - is it just a later phase as the plasma cools down?
- ◆ Is it Comptonized gamma-ray emission? (Optical depth dependent on mass and expansion velocity of the ejecta. A continuum spectrum should be observed).
- ◆ Are the hard X-rays produced in the material flowing from the WD, while a large part of the ejecta are instead from the secondary? (Bob Williams 2013)
- ◆ Question of iron lines at all wavelengths – there should not be iron lines in the ejecta X-ray spectrum, example of V382 Vel.
- ◆ Connection with “soft” emission line spectrum observed at later phases – again, is it just the same region which is cooling?

Bob William's view of nova ejecta (based on V382 Vel)

NuSTAR can observe “prompt” (or later) hard X-rays:

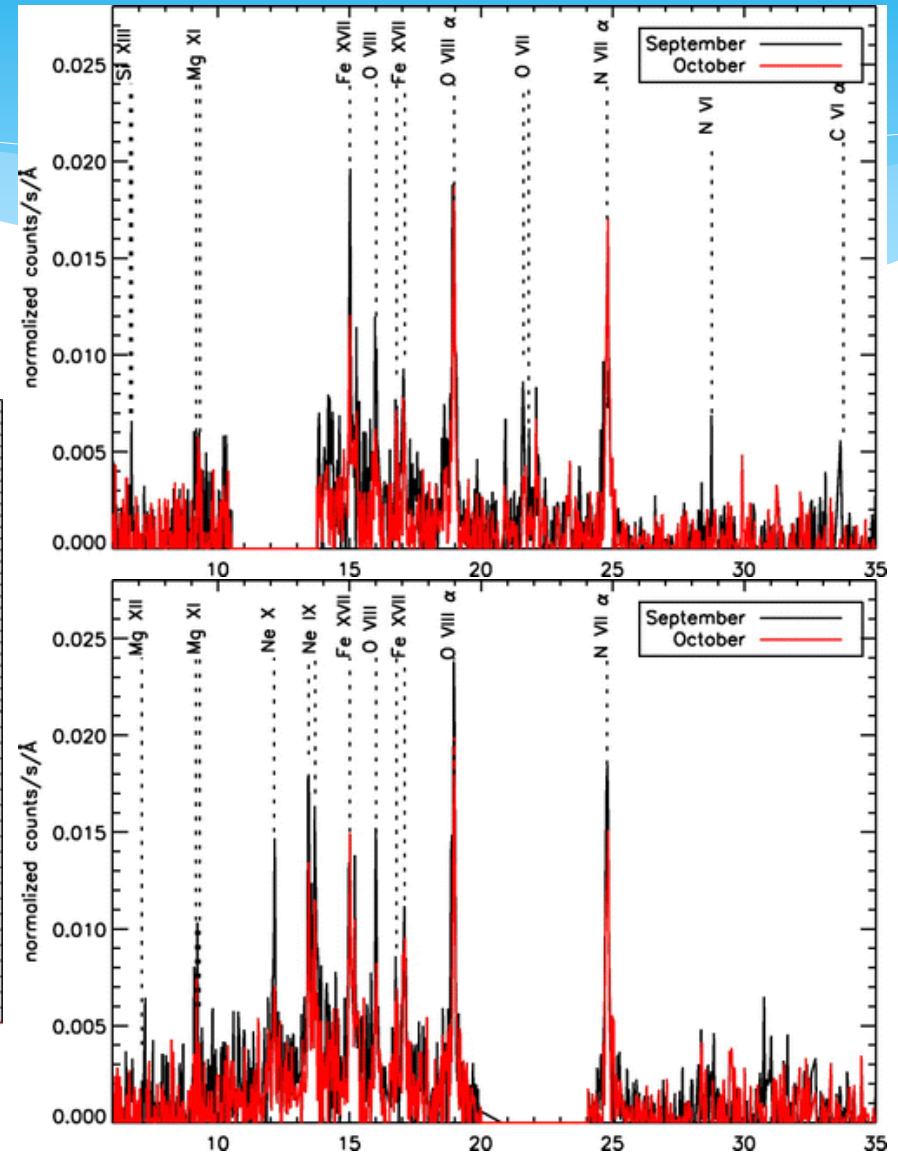

This prominent Iron feature seems to rule out both the Comptonization of gamma rays, and the use of hard X-rays as a probe of the two-ejecta model

RS Oph: an example

How do we go from this

To this →

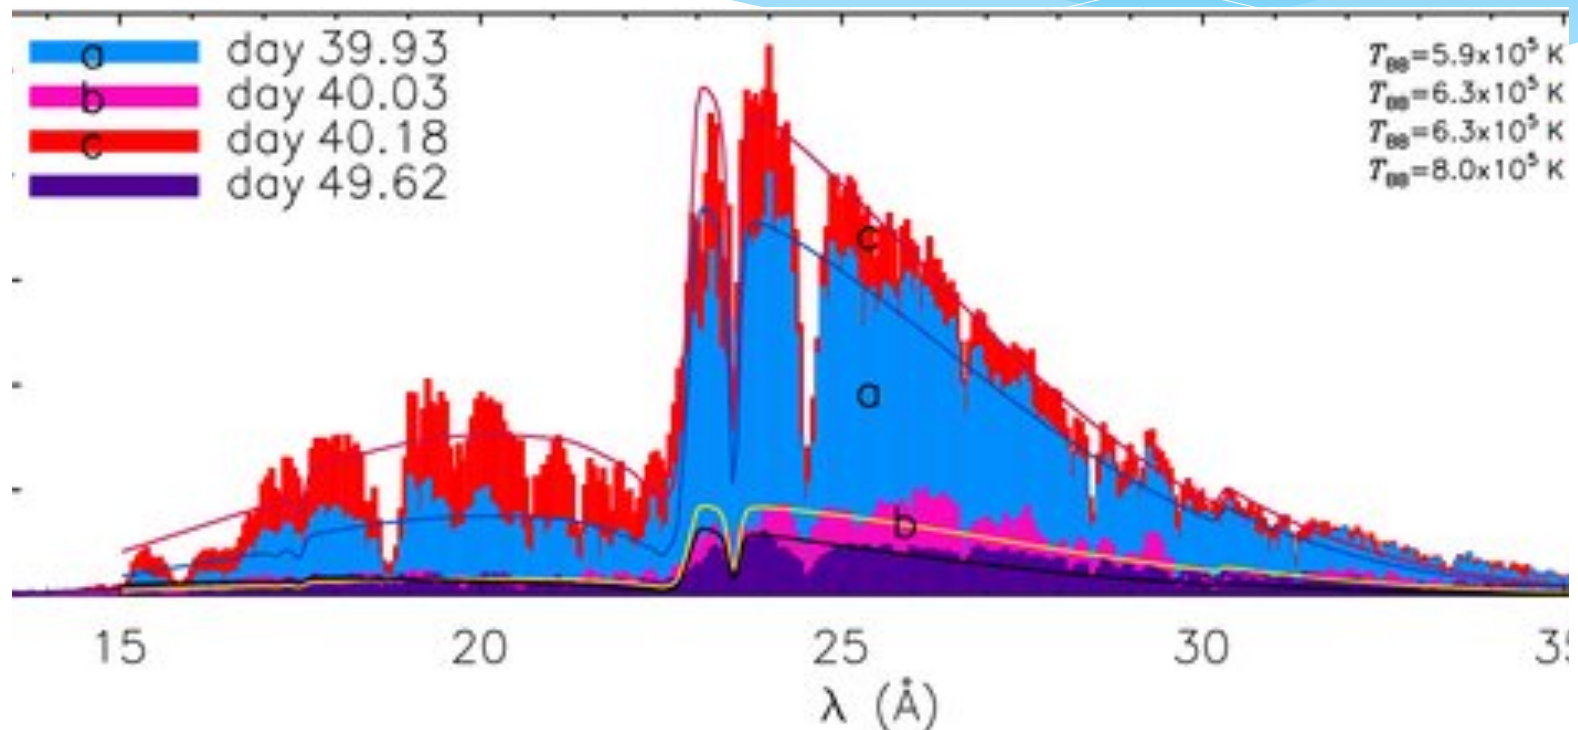

Hypothesis of inclination dependence does not explain two types of spectra in the same nova: RS OPh., and N LMC 2009 changed spectrum, T Pyx had low inclination

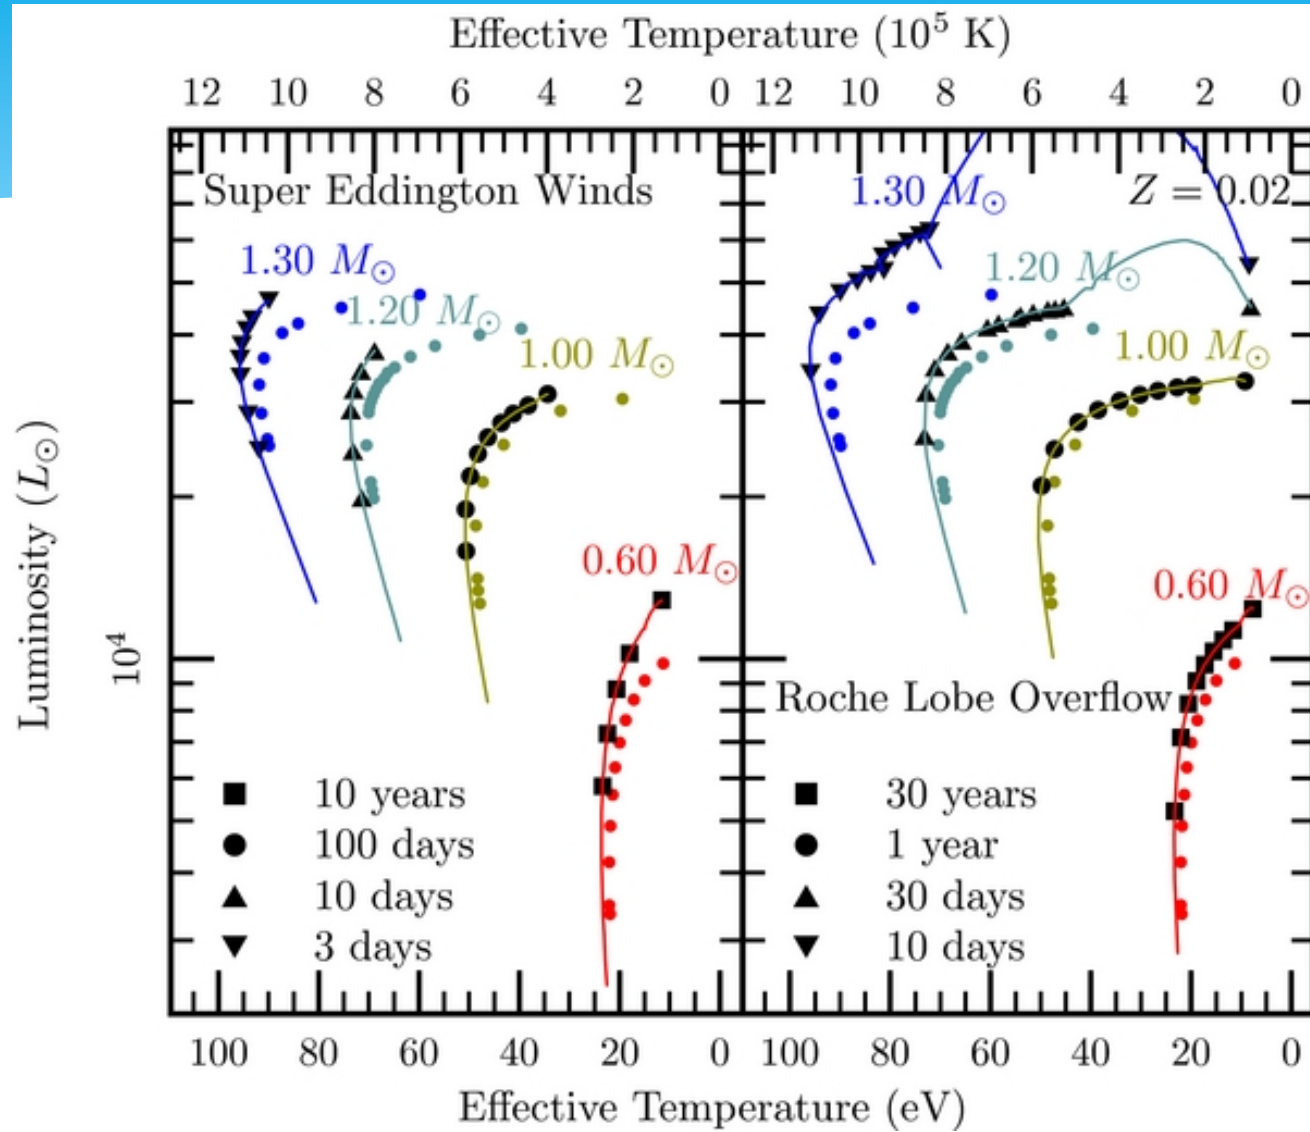

The X-ray emission in the ejecta is (usually) not photoionized:

- ◆ “Smoking gun” of RRC (radiative recombination continua) is usually absent
- ◆ Line ratios MOSTLY (not always) consistent with collisional ionization
- ◆ Plasma temperature appears to be cooling with time
- ◆ Shocked ejecta, also when no red giant wind or symbiotic nebula is present (changing wind velocity, different episodes of mass ejection?)
- ◆ The emission lines are BROAD and blue-or red-shifted

V2491 Cyg one of the best examples of the WD atmosphere and its large variability:

Ness et al. 2011: XMM-Newton RGS gratings spectra of Nova 2491 Cyg in 2010

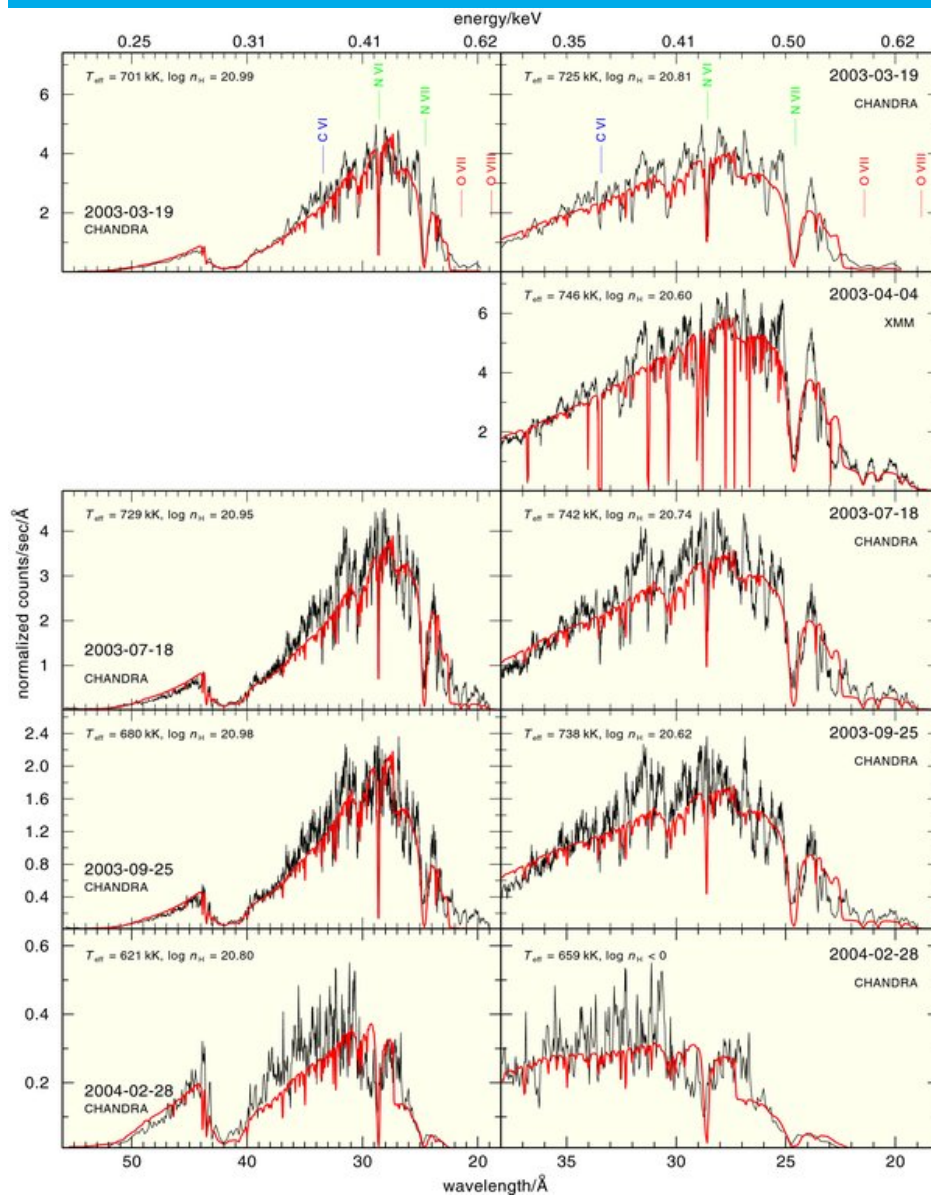

- ✧ Peak effective temperature obtained with Rauch's models' fits shows expected dependence on $t(\text{turn-off})$ and t_2 . The spread with respect to a linear relationship is expected to be due to \dot{m} ,
- ✧ PLAN: try an evaluate \dot{m} for the novae in the plot as they return to quiescence. BUT: is \dot{m} constant? Can it be? We should be able to use T_{eff} as a proxy for the mass: it is very important to test the models and paths towards SN Ia evolution.
- ✧ T Pyx does not fall "well" in these plots.

Atmospheric models

- * Problem of detangling the two components: can be done. WD atmosphere may have some emission lines as well.
- * At least up to a certain post-outburst epoch, the absorption lines are blue-shifted! By as much as ~ 2000 km/s.
- * Rauch's Tuebingen models: static, non LTE plane parallel approximation yields the lines we observe with realistic broadening and abundances... no blue shift
- * van Rossum's wind-atmosphere expanding atmosphere model very interesting but still only grid with solar abundances: does not fit observations.
- * Problem of blue-shifts: observed when theory and "other observations" indicate or prescribe that the NOVA WIND has ceased. Why this residual low \dot{m} wind?

Comparison with Van Rossum

$$T_{\text{eff}} = 550 \text{ K}, \log(g) = 8.18$$

$$T_{\text{eff}} = 550 \text{ K}, \log(g) = 8.18$$

$$T_{\text{eff}} = 550 \text{ K}, \log(g) = 8.18$$

$$T_{\text{eff}} = 550 \text{ K}, \log(g) = 8.44$$

$$T_{\text{eff}} = 475 \text{ K}, \log(g) = 8.48$$

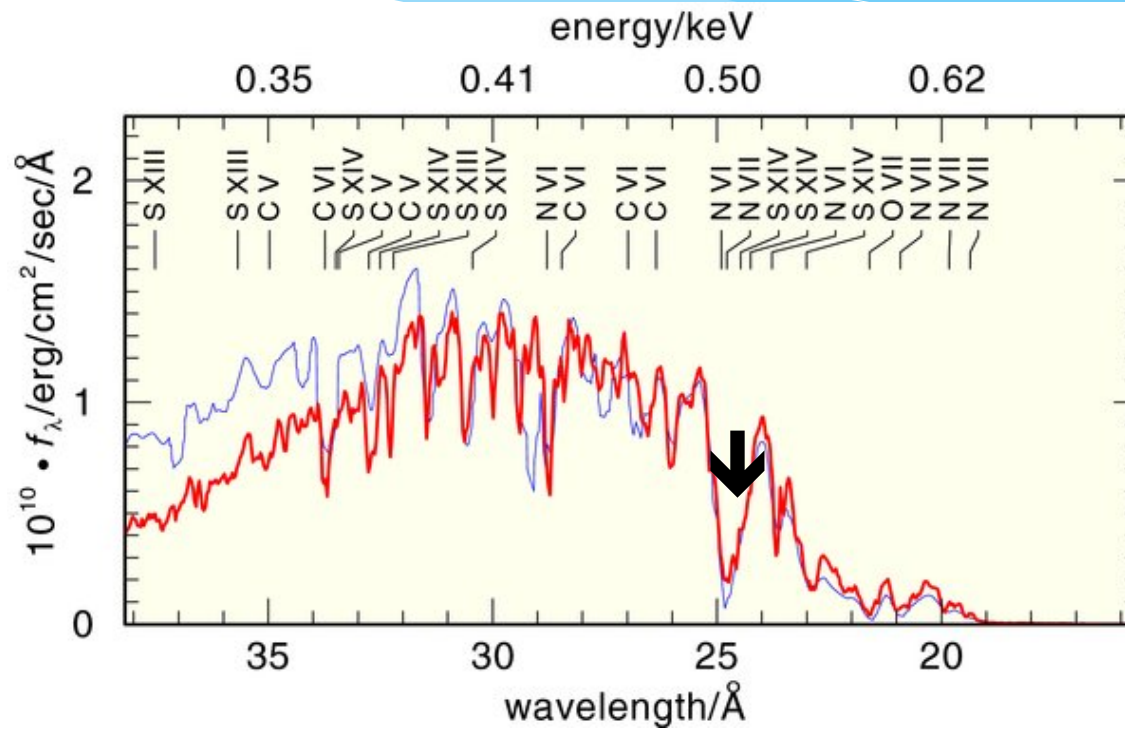

If the atmosphere is expanding:

- * $T(\text{WD})$ at max still depends on $m(\text{WD})$, but there is a “mass degeneracy”: the same $T(\text{eff})$ is reached at more than one value of effective gravity
- * $\dot{m}(\text{wind})$ additional parameter
- * No real handle on \dot{m} , since the few pseudo-P-Cyg profiles observed seem to be due to a chance almost-superposition of red-shifted lines in the ejecta
- * So, hard to quantify the effect of atmospheric expansion... late observations do end when blue-shift ceases

In two cases we did NOT measure a near Eddington luminosity from the WD continuum:

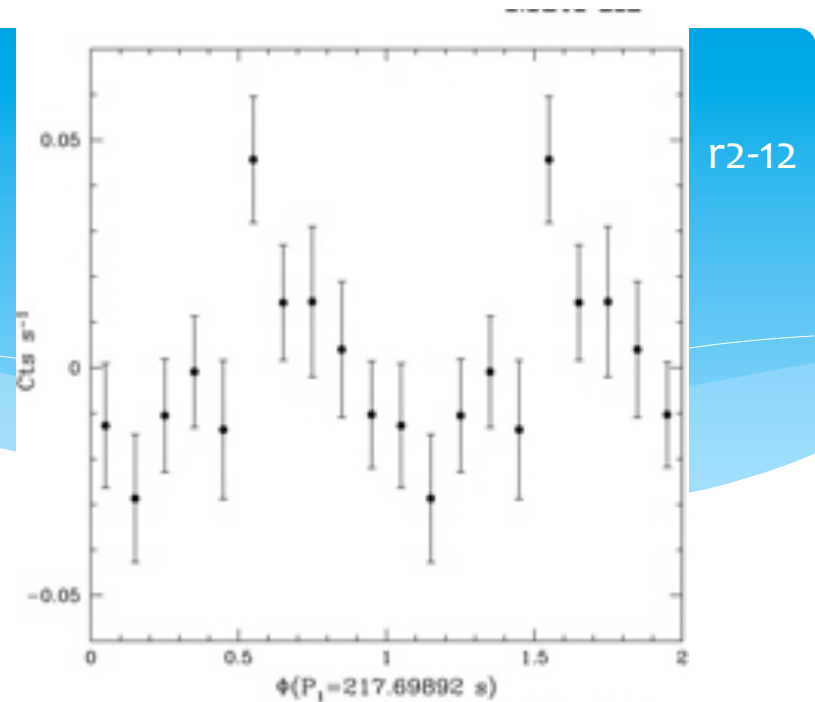

- * U Sco: eclipse observed in X-rays shows low luminosity ($\sim 10^{36}$ erg/s instead of a few 10^{37} erg/s) continuum eclipsed by disk, emitting region very extended: Thomson scattering corona (it preserves the spectrum).
- * T Pyx: not an eclipse system, but X-ray flux much reduced: is part of the view to the WD blocked by highly inhomogeneous ejecta with peculiar geometry?

Abundances: clearly non-solar, only one
“clear” O Ne WD, extremely low C/N

Periodic variability

- * ~half hour periods (e.g. previous slide): non-radial g-mode oscillations?
- * Period due to the WD rotation (V4743 Sgr seems to show both)
- * In RS Oph, KT Eri, and perhaps V1974 Cyg, periods of ~35 sec are observed: very short WD spin. Is this the spin of the WD spun up by accretion?
- * Orbital variability: hours (up to 1.5 days). Are the magnetic fields playing a role in this variability?
- * Flares repeated at each orbital period: are they common?
- * Note two M31 SSS in plots on the right, with same periods as Galactic sources!

Nova Mon 2012: another “Fermi nova” with initially hard X-rays

- ◆ Relatively slow development with SSS emerging only after 5 months, off after 2 months
- ◆ Near main sequence secondary
- ◆ NeO nova
- ◆ Bipolar outflows (Shore et al. 2012)
- ◆ 7.1 hours period detected with Swift XRT and UVOT (Page 2013)
- ◆ “Beautiful” collisionally ionized plasma

Spectral fits:

- * Like RS Oph, started with a “hard” spectrum
- * Shifted to lines of lower and lower ionization potentials in December (our LETG spectrum)
- * Can be fitted with \sim atmosphere at $\sim 600,000$ K + 80 eV + ~ 600 eV plasma

Importance of XMM-Newton for these studies

- ◆ Possibility to observe broad-band and high resolution simultaneously
- ◆ => Obtain high S/N light curve with EPIC and better understand the root cause of the variability
- ◆ Larger effective area: not all novae are luminous enough, and EPIC-pn is the only broad band instrument that may distinguish a “scattered-reflected” or partially obscured WD atmosphere from the “soft” ejecta
